Key points

Question: Do muscle strength and muscle mass predict hospital length of stay (LOS) in patients with moderate to severe COVID-19 patients?

Findings: In this prospective observational study that included 186 hospitalized patients with moderate to severe COVID-19, we observed that LOS was shorter among patients in the highest tertile of strength (assessed by handgrip) vs. those in the mid/lowest tertiles (crude Hazard Ratio [HR]: 1.54, 95%CI: 1.12-2.12). In addition, LOS was longer among patients in the lowest tertile of muscle cross-sectional area (assessed by ultrasound imaging) vs. those in the mid/highest tertiles (HR: 0.69, 95%CI: 0.50 – 0.95).

Meaning: Muscle strength and mass assessed on hospital admission are predictors of LOS in patients with moderate to severe COVID-19, suggesting that muscle health may be protective in this disease.

Abstract

Importance: Strength and muscle mass are predictors of relevant clinical outcomes in critically ill patients, but in hospitalized patients with COVID-19 remains to be determined.

Objective: To investigate whether muscle strength or muscle mass are predictive of hospital length of stay (LOS) in patients with moderate to severe COVID-19.

Design: Prospective observational study.

Setting: Clinical Hospital of the School of Medicine of the University of Sao Paulo.

Participants: One hundred ninety-six patients were evaluated. Ten patients did not test positive for SARS-CoV-2 during hospitalization and were excluded from the analyses. The sample comprised patients of both sexes (50% male) with a mean age (SD) of 59 (± 15) years, body mass index of 29.5 (± 6.9) kg/m². The prevalence of current smoking patients was 24.7%, and more prevalent coexisting conditions were hypertension (67.7%), obesity (40.9%), and type 2 diabetes (36.0%). Mean (SD) LOS was 8.6 days (7.7); 17.0% of the patients required intensive care; 3.8% used invasive mechanical ventilation; and 6.6% died during the hospitalization period.

Main outcome: The outcome was LOS, defined as time from hospital admission to medical discharge.

Results: The crude Hazard Ratio (HR) for LOS was greatest for handgrip strength comparing the strongest vs. other patients (1.54 [95%CI: 1.12 – 2.12; p = 0.008]). Evidence of an association between increased handgrip strength and shorter hospital stay was also identified when handgrip strength was standardized according to the sex-specific mean and standard deviation (1.23 [95%CI: 1.06 – 1.19; p = 0.008]). The magnitude of these associations remained consistent and statistically significant after

adjusting for other covariates. Mean LOS was shorter for the strongest patients (7.5 ± 6.1 days) vs. others (9.2 ± 8.4 days). Evidence of associations were also present for vastus lateralis cross-sectional area. The crude HR identified shorter hospital stay for patients with greater sex-specific standardized values (1.17 [95%CI: 1.01 – 1.36; $p = 0.037$]); however, we found increased uncertainty in the estimate with the addition of other covariates (1.18 [95%CI: 0.97 – 1.43; $p = 0.092$]). Evidence was also obtained associating longer hospital stays for patients with the lowest values for vastus lateralis cross-sectional area (0.69 [95%CI: 0.50 – 0.95; $p = 0.025$]). Mean LOS for the patients with the lowest muscle cross-sectional area was longer (10.8 ± 8.8 days) vs. others (7.7 ± 7.2 days).

Conclusions and Relevance: Muscle strength and mass assessed upon hospital admission are predictors of LOS in patients with moderate to severe COVID-19, which stresses the value of muscle health in prognosis of this disease.

Introduction

Aging and chronic conditions such as type 2 diabetes increase the risk of developing severe forms of COVID-19. Nevertheless, apparently healthier, younger individuals may also require hospitalization and develop poor outcomes¹⁻³. This suggests that there might be undiscovered clinical features associated with COVID-19 prognosis, with muscular parameters being potential candidates.

Skeletal muscle constitutes ~40% of total body mass and plays a pivotal role in different physiological process such as immune response, regulation of glucose levels, protein synthesis, and basal metabolic rate⁴⁻⁶. Handgrip strength and muscle mass have been shown previously to be predictive of clinical outcomes, such as hospital length of stay (LOS) and mortality, in distinct populations⁷⁻¹⁰. The prognostic value of skeletal muscle parameters among hospitalized patients with COVID-19 remains to be determined. Herein, we investigated whether muscle strength and muscle mass assessed at hospital admission are predictive of LOS in patients with moderate to severe COVID-19

Methods

Study design

This is a prospective observational study conducted between March 2020 and October 2020 in the Clinical Hospital of the School of Medicine of the University of Sao Paulo in Brazil (HCFMUSP) the largest quaternary referral teaching hospital in Latin America. This study was approved by the local Ethics Committee (Ethics Committee Approval Number (31303720.7.0000.0068)). All patients provided written informed consent before entering the study. This manuscript was reported according to

the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) Statement.

Participants

The inclusion criteria were: 1) aged 18 or older; 2) diagnosis of COVID-19 by PCR for SARS-CoV-2 from nasopharyngeal swabs or computed tomography scan findings (bilateral multifocal ground-glass opacities $\geq 50\%$) compatible with the disease; 3) diagnosis of flu syndrome with hospitalization criteria on hospital admission, presenting respiratory rate ≥ 24 breaths per minute, saturation $< 93\%$ on room air or risk factors for complications, such as heart disease, diabetes mellitus, systemic arterial hypertension, neoplasms, immunosuppression, pulmonary tuberculosis, and obesity, followed by COVID-19 confirmation. Exclusion criteria were: 1) cancer in the past 5 years; 2) delirium; 3) cognitive deficit that precluded the patient from reading and signing the informed consent form; 4) prior diagnosis of muscle degenerative disease (e.g., myopathies, amyotrophic lateral sclerosis, stroke); 5) patients already admitted under invasive mechanical ventilation. Patients who met these criteria were considered to have moderate to severe COVID-19.

Data collection

All patients were evaluated in the point-of-care within less than 48 hours upon hospital admission for handgrip strength and vastus lateralis cross-sectional area, by means of ultrasound imaging, and were followed until medical discharge.

Handgrip strength assessments were performed with the patient seated holding the dynamometer (TKK 5101; Takei, Tokyo, Japan) with the dominant hand and elbow positioned at a 90° angle. Three maximum attempts of 5 seconds with 1 minute of the interval between attempts were performed and the best result was used for analysis.

Vastus lateralis cross-sectional area was assessed by a B-mode ultrasound with a 7.5-MHz linear-array probe (SonoAce R3, Samsung-Medison, Gangwon-do, South Korea) as previously described¹¹. Cross-sectional area analyses were performed in a blinded fashion by a single investigator using ImageJ (NIH, USA). Demographic, clinical, and biochemical data of the patients were obtained through medical records.

Outcome and stratification of patients

Our primary outcome was LOS, defined as time (days) from hospital admission to medical discharge. Patients who died during the hospitalization period were right-censored in the LOS analysis. To examine whether muscle strength or mass were predictive of LOS, we ranked patients according to handgrip strength and vastus lateralis cross-sectional area into sex-specific tertiles. Then, we compared the highest tertile (High) vs. the combined mid and lowest tertiles (High vs. Other), and the lowest tertile (Low) vs. the combined mid and highest tertiles (Low vs. Other)

Sample size and statistical analyses

An a-priori sample size estimate was made to achieve small optimism in the predictor effect estimates as defined by a global shrinkage factor of 0.9¹². The expected shrinkage is conditioned on the sample size (n), the total number of predictors (p) and a generalization of the proportion of variance explained for multivariable models with time-to-event outcomes ($R_{CS_app}^2$)¹². For the present study p was set to 6 and $R_{CS_app}^2$ to 0.5 based on findings from previous research^{7, 13, 14} and therein, indicating a required sample size of n = 184. Guided by this estimate, a total of 196 patients were evaluated during their hospital stay.

The outcome (LOS) was analyzed with multivariable Cox proportional baseline hazard models and adjusted for sex (male or female), age group (18-35, 36-55 or ≥ 56),

obesity ($BMI < 30$ or $BMI \geq 30$), oxygen support at admission (0-4L, 5-9L, ≥ 10 L) and Type 2 diabetes (yes or no). Both crude and adjusted hazard ratios (HRs) were estimated for handgrip strength and vastus lateralis cross-sectional area. Each predictor was assessed as both a discrete and continuous predictor. Discrete models were conducted by calculating sex-specific tertiles and then focusing on either the largest tertile (High vs. Other) or the smallest tertile (Low vs. Other). Continuous models were conducted by standardizing predictor values relative to the sex-specific mean and standard deviation. HRs were accompanied with corresponding 95% confidence intervals (95%IC), with all analyses performed in the statistical environment R (version 3.5.3; R Core Team 2020) with the survival¹⁵ and survminer¹⁶ packages.

Results

Patients

One hundred ninety-six patients were evaluated. Ten patients did not test positive for SARS-CoV-2 during the hospitalization period and were excluded from the analyses. Table 1 shows the demographic, biochemical, and clinical characteristics of the patients. Overall, 86% (160 of 186) had a positive PCR test for SARS-CoV-2 at the enrollment, and 42% had computed tomography scan findings suggestive (i.e., pulmonary commitment $\geq 50\%$) for COVID-19. All the remaining patients (26 of 186) had the diagnosis confirmed by serology assay to detect IgG against SARS-CoV-2 at some point during the hospital day. The sample comprised patients of both sexes (50% male) with a mean (SD) age of 59 years (± 15), body mass index of 29.5 kg/m^2 (± 6.9). The prevalence of current smoking patients was 24.7%, and more prevalent coexisting conditions were hypertension (67.7%), obesity (40.9%), and type 2 diabetes (36.0%).

The signs and symptoms more commonly observed at admission were dyspnea (81.2%), cough (64.4%), fever (57.5%), myalgia (26.9%), fatigue (25.3%), headache (22.0%), anosmia (19.9%), diarrhea (17.7%), dysgeusia (17.2%), nausea (11.3%), abdomen pain (10.2%), chest pain (10.2%), vomiting (9.7%), runny nose (9.1%), earache (4.3%), and dizziness (1.1%). Mean (SD) LOS was 8.6 days (7.7); 17.0% of the patients required intensive care; 3.8% used invasive mechanical ventilation; and 6.6% died during the hospitalization period.

Primary Outcome

The crude HR for time from hospital admission to discharge was greatest for handgrip strength comparing the strongest vs. other patients (1.54 [95%CI: 1.12 – 2.12; $p = 0.008$]). Evidence of an association between increased handgrip strength and shorter hospital stay was also identified when handgrip strength was standardized according to the sex-specific mean and standard deviation (1.23 [95%CI: 1.06 – 1.19; $p = 0.008$]). The magnitude of these associations remained consistent and statistically significant after adjusting for other covariates (Table 2). Mean LOS was shorter for the strongest patients (7.5 ± 6.1 days) vs. others (9.2 ± 8.4 days).

Evidence of associations were also present for vastus lateralis cross-sectional area. The crude HR identified shorter hospital stay for patients with greater sex-specific standardized values (1.17 [95%CI: 1.01 – 1.36; $p = 0.037$]); however, we found increased uncertainty in the estimate with the addition of other covariates (1.18 [95%CI: 0.97 – 1.43; $p = 0.092$]). Evidence was also obtained associating longer hospital stays for patients with the lowest values for vastus lateralis cross-sectional area (0.69 [95%CI: 0.50 – 0.95; $p = 0.025$]). Mean LOS for the patients with the lowest muscle cross-sectional area was longer (10.8 ± 8.8 days) vs. others (7.7 ± 7.2 days).

Discussion

In this prospective observational study, we found muscle strength (as assessed by handgrip) and muscle mass (as assessed by vastus lateralis cross-sectional area) are predictive of LOS in hospitalized patients with moderate to severe COVID-19. To the best of our knowledge, this is the first study to demonstrate the prognostic value of these skeletal muscle parameters in this disease.

A recent study demonstrated that the Clinical Frailty Score (CFS) independently predicted time to medical discharge and mortality in COVID-19 patients¹³. Despite the value of these findings, it is noteworthy that the CFS is a judgement-based frailty tool that relies highly on experience and training for proper categorization of the patients. Moreover, CFS is ultimately an indirect measure of functional status and is mainly used in geriatric patients. These are factors that might limit the reliability of CFS in real-life clinical scenarios. Conversely, handgrip strength is a simple, direct, easy handling, low-cost measurement commonly utilized in the clinical setting as an indicator of the general health status in individuals across a wide age range. Indeed, handgrip strength assessed at hospital admission have been shown to be a predictive measure of LOS and mortality in distinct populations⁷⁻¹⁰. Our findings extend this knowledge to patients admitted into the hospital with acute COVID-19 symptoms, by showing that stronger patients had lower LOS than their weaker counterparts.

Muscle mass is also considered as an indicator of general health status^{17, 18}. Previous studies have suggested that low muscle mass (assessed by mid-arm circumference, calf circumference, and estimated by anthropometric equations) may predict mortality among elderly^{17, 18}. In the current study, we directly assessed, in the point-of-care, vastus lateralis cross-sectional area using ultrasonography among patients with COVID-19. Our findings suggest that low muscle mass could contribute to higher

LOS among COVID-19 patients During a critical illness, net breakdown of muscle protein is stimulated to provide abundant amino acids to meet these increased demands of tissues such as immune cells and liver ¹⁹. In this context, patients with limited muscle mass reserves would presumably be more vulnerable to stress factors, such as severe burn injuries and cancer ^{20, 21}. The present findings suggest that this could be the case of COVID-19.

Muscle mass plays a key role in recovery from critical illness, whereas muscle strength and function are key to the recovery process ²². If there is a preexisting deficiency of muscle mass before the onset of an acute illness, one may speculate that the expected loss of muscle mass and function associated with hospitalization may push the patient over a threshold that makes recovery of normal function unlikely to ever occur ²². The impact of this physiopathological mechanism on long-term effects of COVID-19 (long COVID) remains to be explored.

Limitations

First, the longitudinal design of this study does not allow causative conclusions. Second, although this study was adequately powered to detect changes in the selected outcomes, this was still a small cohort composed by patients with heterogeneous clinical features, medication regimen and disease manifestations, possibly subject to unmeasured confounders. While the Cox proportional hazards models were controlled for several potentially confound variables, direct sub-group comparisons were not possible due to sample size constraints. Third, our results are confined to patients with moderate to severe COVID-19 and should be read with care regarding other clinical settings. Finally, the minimal clinically important difference in LOS among patient with COVID-19 is yet unknown, which limits the ability to make clinical inferences about the present findings.

Conclusions

Muscle strength and mass assessed on hospital admission are predictors of LOS in patients with COVID-19. While it is unknown whether these muscular parameters add to the prognostic value provided by the more established and accepted predictors that already have been identified²³, the present data suggest that muscle health may benefit patients with moderate to severe COVID-19. The evidence provided by this study paves the way for randomized controlled trials to test the utility of preventive or in-hospital interventions in shortening LOS among these patients through improving muscle mass and/or function.
